

UNICITY LABS · A SETTLEMENT SUBSTRATE · SEED

THE FIRST RAIL WHERE THE CREDENTIAL LIVES **INSIDE** THE TRANSFER.

A thirty-year campaign to give people fair access – cut the middleman, prove the identity, move the value freely. One piece was always missing: a settlement layer where the credential is **inside the transaction, not beside it**. That layer now exists.

TALLINN · ZUG · ABU DHABI

EVERY BET ASSUMED A LAYER **NONE** **OF THEM OWN.**

- Cut the middleman – value moves directly, no slow intermediary **SHIPPED**
- Move the value – at the speed of a message, 24/7 **SHIPPED**
- Prove the identity – SSI / verifiable credentials, a generation of attempts **NEVER LOAD-BEARING**

The credential always sat next to the transaction. **Nothing broke if you skipped it.**

Fair access needs three things to be real. Two have been shipped for decades. The third – identity that **cannot be skipped** – is the piece the rails themselves never carried.

THE TEAM THAT BUILT THE BACKBONE A NATION RUNS ON.

The team built Guardtime / KSI – the cryptographic backbone running across Estonian e-government since 2012, eIDAS-aligned. The same KSI architecture sustained **300,000+ payments per second** in the Eesti Pank 2021 CBDC experiment.

Settlement infrastructure proven at the scale of a state – **not a throughput claim about Unicity.**

2012

KSI live across Estonian e-government – in production since

300,000+ tx/sec

EU trust-services environment – government-grade

THE BUYER THAT FORCES THE LAYER HAS ARRIVED.

57.5%

OF WEB REQUESTS ARE AUTOMATED – NOT ON-CHAIN (CLOUDFLARE, 2026)

Two facts, kept separate. The majority actor on the internet is already a machine. And those machines have started paying – roughly **100M x402 transactions on Base in nine months** (Chainalysis); real volume still tiny.

x402 works – but it is fifteen steps of facilitators and settlement. When the asset moves peer-to-peer, the message is the settlement.

An agent cannot round-trip a centralized check. **It verifies in-band, at the edge – or it cannot transact at all.**

RIGHT THESIS. NO FORCING FUNCTION.

Self-sovereign identity was correct, and early.

It did not fail on cryptography. It stalled because the credential always sat **next to** the transaction – never inside it.

Skip the check and nothing breaks – there was never an economic reason to carry the credential.

Microsoft retired **did:ion** in December 2023. Trinsic wound down before a single credential was ever reused. SSI scaled linearly, then flattened.

GlobaliD never reached escape velocity; its mission migrated forward into USBC. Not a failure of the idea – a failure of the rails to make the idea **unskippable**.

The missing piece was never better identity. **It was a settlement layer where the asset refuses to move without it.**

THE FLOOR UNDER 250 BETS.

Bets across identity, payments, exchanges, compute, and banking – each one assuming a settlement layer it does not own.

IDENTITY WHO CAN ACT	GlobaliD · Indicio · Terminal 3
PAYMENTS & RAILS HOW VALUE MOVES	Ripple · Square · Robinhood
EXCHANGES & CUSTODY WHERE VALUE IS HELD	Coinbase · Uphold
DATA · COMPUTE · SPEED WHAT IT RUNS ON	Filecoin · Solana · Brave
BANKING & TOKENIZED MONEY MONEY WITH RULES INSIDE	Vast Bank · USBC
SETTLEMENT SUBSTRATE WHAT IT ALL SETTLES ON	UNICITY – the layer none of the bets occupy, and the one they all silently assume

PRIVACY, COMPLIANCE, THROUGHPUT. **PICK TWO.**

On a shared ledger every transaction is public – easy to audit, impossible to keep private.

Add cryptography to win privacy back and throughput collapses – down to one transaction a second. The privacy tech kills the speed.

Machine-speed money needs all three at once. On a shared ledger, you cannot have them.

So we didn't optimize the ledger. We removed the thing that forces the tradeoff.

MAKE THE MONEY A THING YOU HOLD – NOT AN ENTRY SOMEONE KEEPS.

Today a stablecoin is a row on a shared ledger – every participant maintains it, every transfer asks the ledger's permission. The move is simple: take that entry and make the asset a **self-contained file**. A native data type, not a row. It moves agent-to-agent like cash – and the chain's only remaining job is to prove it wasn't spent twice.

Satoshi titled it peer-to-peer electronic cash. Seventeen years later it is neither. This is.

VERIFY IT YOURSELF. LIKE CASH.

When someone hands you a \$10 note, you don't send it to a committee to ask if it's real – you check it yourself. A Unicity token works the same way: it carries its own proof. It moves agent-to-agent, and the recipient verifies it **on arrival** – no chain to call, no ledger to ask.

The proof travels with the asset. The transfer needs no one's permission.

THE CHAIN'S ONLY JOB IS TO PREVENT DOUBLE-SPENDING.

That was always the point – not validation, not global order. Just one question: **has this token been spent?** The uniqueness oracle answers yes or no, and never sees the transaction.

It isn't validating transactions anymore, so the work collapses – and the burden of proof moves to the recipient.

Three layers: consensus secures the base, the oracle stores only uniqueness proofs, execution happens client-side and off-chain.

| A blockchain reduced to its **one irreducible job**.

COMPLIANCE BY CONSTRUCTION. NOT A GUY IN THE MIDDLE.

Coinbase's agent-payment standard works – with a facilitator in the middle, watching every transaction. We put the rule **inside the token**. Each token carries its own predicate – who may receive it: KYC, jurisdiction, accreditation. The transfer will not complete unless the recipient satisfies it. No monitor, no middleman to bypass. The predicate checks a self-contained attestation in-band – no issuer callback at settlement.

The credential isn't checked at the door. It is the door.

On a shared ledger, atomicity is free – a contract executes or it doesn't. Off-chain, both legs must settle with no middleman holding the float. The HTLC's answer is a timer and a grieving window. Ours: both parties commit independently – the swap completes, or everyone keeps their token.

THE UNICITY TRUSTLESS ATOMIC SWAP

Both parties commit independently – the swap completes, or everyone keeps their token.

HASHED TIMELOCK (HTLC)

- 1 · A locks, reveals hash y
- 2 · B locks against same y
- 3 · A claims, revealing preimage x
- 4 · B must claim before timeout

THE TIMING TRAP

B late on step 4 – a dropped connection – and A keeps both.

UNICITY PREDICATE SWAP

YOU ALREADY REACHED THIS CONCLUSION. YOU BUILT IT INSIDE ONE BANK.

“Identity in itself is not that interesting. It's what you can do with it.” → A credential only does something if the asset cannot move without it.

USBC's tokenized deposit is a U.S.-dollar bank deposit with identity embedded in it – identity inside the money, on an OCC-chartered bank, explicitly not a synthetic stablecoin. That is the receive predicate, discovered the hard way, on a single charter.

DON'T TAKE OUR WORD FOR IT. HERE'S THE MATH.

The white paper is marketing – we cringe at it. These three are math. Drop them into any model and it will prove the protocol to you: no double-spend, service- and user-side privacy, trustless swaps.

SYSTEMS ENGINEERING

Unicity Infrastructure: the Aggregation Layer – off-chain & offline tokens; ZK proofs, no trusted setup.

github.com/unicitynetwork/aggr-layer-paper

SECURITY PROOF

The Unicity Execution Layer – no double-spend; no blocking; service & user-side privacy.

github.com/unicitynetwork/execution-model-tex

PREDICATES & SWAPS

Unicity: Predicates & Atomic Swaps – programmable predicates; trustless atomic swaps.

github.com/unicitynetwork/unicity-predicates-tex

What's proven is **privacy and no-double-spend**. Scalability is by sharding – stated as the design, not claimed as a benchmark.

A CHARTER SETTLES FOR ITS MEMBERS. THE SPACE **BETWEEN CHARTERS** HAS TO BE BUILT.

THE STRONGEST VERSION OF THE ARGUMENT

“A permissioned chain on one bank charter already puts identity inside the money – USBC proves it works. Why generalize?”

- 1 USBC proves the conclusion: identity belongs inside the money. **It works.**
- 2 A charter settles for the parties on that charter. Value can't round-trip to a counterparty banking somewhere else without a trusted middle – **the boundary a charter cannot cross by construction.**
- 3 An agent at machine speed cannot phone any single charter's verifier in-band. Cross-charter, cross-agent settlement is the one thing a charter structurally can't do – **no matter how good the charter.**

Unicity is the layer that lets a USBC deposit settle to a counterparty on a different charter. **USBC reached it on one charter; this generalizes the move – it doesn't replace it.**

AGENTS DISCOVER, TRANSACT, AND SETTLE **TODAY.**

A running demonstration, not a forecast – agents post intents to a shared board, transact peer-to-peer, and settle on the substrate now.

The uniqueness oracle is live and open-source; the repos are public – and honestly, a bit of a mess. We're protocol engineers – we'll show you exactly what runs and what's still being built.

Pipeline: sovereign and stablecoin-issuer engagements in confidential discussions – references on request.

The architecture isn't a roadmap slide. The primitive runs.

ONE LAYER DOWN FROM WHERE THE THESIS **ALREADY ARRIVED.**

Identity inside the money. Compliance that travels with the asset. Settlement with no shared ledger. The conclusion USBC reached on one bank charter – generalized to a layer any issuer can settle on. Not a vendor. Not another L1 chasing throughput. The settlement layer for machine commerce – the chain only prevents double-spend; everything below it is the substrate.

Raising **\$5M Seed** · \$25M cap / \$50M token FDV · SAFE + token warrant.

The proof is the partnership: a **Vast / USBC tokenized deposit whose receive predicate is a USBC attestation** – identity inside the money, settling on a layer that enforces it. One layer down.

THE IDEA IS ALREADY VALIDATED – ON ONE CHARTER. **THIS IS THE LAYER THAT LETS IT HOLD EVERYWHERE.**

ARCHITECTURE, NOT POLICY · PROOF, NOT PROMISES.
